1 Introduction

1.1 Overview

Lepton (short for “lightweight expression parser”) is a C++ library for parsing, evaluating, differentiating, and analyzing mathematical expressions. It takes expressions in the form of text strings, then converts them to an internal representation suitable for evaluation or analysis. Here are some of its major features:

- Support for a large number of standard mathematical functions and operations.
- Support for user defined custom functions.
- A variety of optimizations for automatically simplifying expressions.
- Computing analytic derivatives.
- Representing parsed expressions in two different forms (tree or program) suitable for further analysis or processing.

It is typically used in one of two ways. One case is that you use it to evaluate expressions. This is very easy to do, and is described in the next section.

The other case is that you want to process expressions yourself in some more advanced way. In particular, Lepton was originally created for use in the OpenMM project (<https://simtk.org/home/openmm>). In OpenMM, Lepton is used to parse expressions, differentiate them, and convert them to a representation that is easier to process. OpenMM then transforms that representation into OpenCL source code, allowing them to be evaluated on a graphics processor as part of a molecular simulation.

1.2 Basic Usage

If all you want to do is evaluate mathematical expressions, this section tells you everything you need to know. You can skip the rest of the manual, except for Appendix A which describes the syntax for expressions and lists the supported functions and operators.

Here is the code to evaluate a simple expression:

```
#include "Lepton.h"
...
double value = Lepton::Parser::parse("sqrt(9)-1").evaluate();
```

To evaluate an expression that involves variables, create a `std::map` containing values for the variables:

```
std::map<string, double> variables;
variables["x"] = 2.0;
variables["y"] = 3.0;
double value = Lepton::Parser::parse("x^y").evaluate(variables);
```

If you plan to evaluate an expression many times with different values for the variables, this is the most efficient way to do it:

```
Lepton::ExpressionProgram program =
    Lepton::Parser::parse("2*x+1").optimize().createProgram();
// Each time you want to evaluate it, do the following:
double value = program.evaluate(variables);
```

1.3 License

2 Using Lepton

Since you are still reading, you presumably want to do something more than just evaluate mathematical expressions. Let's go through the API in detail and examine how each part of it works.

2.1 Lepton::ParsedExpression

The `Lepton::ParsedExpression` class is the primary internal representation for a mathematical expression. A `ParsedExpression` is created by passing a string to `Lepton::Parser::parse()`.

A `ParsedExpression` represents the expression as a tree of `Lepton::ExpressionTreeNode` objects. Call `getRootNode()` to get the root of the tree. Each node specifies a list of child nodes (obtained by calling `getChildren()` on it) and an operation to perform on them (specified by a `Lepton::Operation` object, obtained by calling `getOperation()` on it).

A `ParsedExpression` is evaluated by hierarchically evaluating all nodes in the tree. To evaluate a node, each of its child nodes is first evaluated. Based on the node's `Operation`, some calculation is then performed on those values to produce the final value.

`Operation` is an abstract class. It has many subclasses, each corresponding to a particular value, function, or operator that can appear in an expression. Some examples are `Operation::Constant` representing a numeric constant, `Operation::Multiply` representing multiplication, and `Operation::Sqrt` representing the square root function.

2.2 Optimization

Lepton can transform a `ParsedExpression` in a variety of ways to allow it to be evaluated more quickly. Simply call `optimize()` on it to create a new, optimized `ParsedExpression`. Here are some examples:

```
cout<<Parser::parse("2*3*x").optimize()<<endl;
```

produces the output

$6 \cdot x$

In this case, it has precomputed the subexpression “2*3”.

```
cout<<Parser::parse("1/(1+x)").optimize()<<endl;
```

$\text{recip}(1+x)$

In this case, it has performed two optimizations. The expression “1+x” involves three nodes: 1, x, and the + operator. It has reduced it to only two nodes: x and an “add constant” operation. It also has replaced “1/” (two nodes) with a single “reciprocal” operation.

```
cout<<Parser::parse("x^(1/2)").optimize()<<endl;
```

$\text{sqrt}(x)$

It first precomputed “1/2” to get 0.5. It then realized that raising something to the 0.5 power is equivalent to taking the square root. This transformation eliminates a node from the tree, and also takes advantage of the fact that the sqrt() function is often implemented in hardware, and therefore is faster to evaluate than generic exponentiation.

Here is an extreme example of the power of optimization:

```
cout<<Parser::parse("log(3*cos(x))^(sqrt(4)-2)").optimize()<<endl;
```

1

It precalculated “sqrt(4)-2”, then recognized that anything raised to the 0th power is equal to 1.

When calling `optimize()`, you can provide values for a subset of the variables that appear in the expression. This is useful when symbols have fixed values. Those symbols can then be replaced with the fixed values, and optimizations can be done based on them.

```
std::map<string, double> constants;
constants["pi"] = M_PI;
cout << Parser::parse("2*pi*x").optimize(constants) << endl;
6.28319*(x)
```

2.3 Differentiation

Lepton can compute the analytic derivatives of expressions. Simply call `differentiate()` on a `ParsedExpression`, specifying the name of the variable to differentiate with respect to. For example, the following code evaluates $d(x^2)/dx$

```
cout<<Parser::parse("x^2").differentiate("x")<<endl;
(( (2) * ( (x) ^ (-1+(2)) ) ) * (1) ) + ( ( (log(x)) * ( (x) ^ (2) ) ) * (0) )
```

If that answer isn't quite what you were expecting, trust me that it really is correct! It just has a lot of completely wasted calculation, such as evaluating " $\log(x)*x^2$ ", then throwing the result away by multiplying it by zero. It still produces the correct result, but if you plan to evaluate it many times, you should call `optimize()` to get a simpler expression:

```
cout<<Parser::parse("x^2").differentiate("x").optimize()<<endl;
2*(x)
```

To calculate higher order derivatives, just call `differentiate()` multiple times.

2.4 Lepton::ExpressionProgram

In addition to `ParsedExpression`, Lepton can represent an expression in a second way: `Lepton::ExpressionProgram`. This consists of a linear sequence of Operations to be executed in order. It is created by calling `createProgram()` on a `ParsedExpression`.

An ExpressionProgram is evaluated using a stack. Initially, the stack is empty. For each Operation in the program, any necessary arguments are popped off the stack, the Operation is evaluated, and the result is pushed back onto the stack. When the end of the program is reached, the stack will contain a single value, which is the value of the expression.

There are two reasons for the existence of this class. First, an expression can be evaluated more efficiently in program form than in tree form. Therefore, if you plan to evaluate an expression many times, it is best to convert it to a program. Second, the program form is more convenient for certain types of analysis. Depending on how you plan to process an expression, you can choose the representation that is most appropriate.

2.5 Lepton::CustomFunction

In addition to the standard mathematical functions supported by Lepton, you can define your own functions that may appear in expressions. To do this, you must define a subclass of the abstract class Lepton::CustomFunction. When you call Parser::parse(), give it a std::map with function names as keys and the corresponding CustomFunctions as values:

```
map<string, CustomFunction*> functions;
WootFunction woot;
functions["woot"] = &woot;
ParsedExpression exp = Parser::parse("7*woot(x)+3", functions);
```

The object stored in the map is used only during parsing; new objects are created by the parser for any nodes that appear in the expression, and those are deleted automatically when the ParsedExpression is deleted. The expression will therefore remain valid even when the variable “woot” goes out of scope.

A subclass of CustomFunction must implement four methods:

```
int getNumArguments() const
```

This method should return the number of arguments expected by the function.

```
CustomFunction* clone() const
```

This method should return a new CustomFunction object (allocated on the heap with the “new” operator) that is a clone of this one.

```
double evaluate(const double* arguments) const
```

This method should evaluate the function. `arguments` is an array containing the values of all arguments to the function.

```
double evaluateDerivative(const double* arguments, const int*  
derivOrder) const
```

This method should evaluate the function’s derivatives. `arguments` is an array containing the values of all arguments to the function. `derivOrder` is an array specifying the number of times the function has been differentiated with respect to each of its arguments. For example, the array `{0, 3}` indicates a third derivative with respect to the second argument.

As a simple example, here is a complete CustomFunction subclass that implements the function $f(x,y) = 2*x*y$:

```
class ExampleFunction : public CustomFunction {  
    int getNumArguments() const {  
        return 2;  
    }  
    CustomFunction* clone() const {  
        return new ExampleFunction();  
    }  
    double evaluate(const double* arguments) const {  
        return 2.0*arguments[0]*arguments[1];  
    }  
}
```

```
double evaluateDerivative(const double* arguments, const int*
derivOrder) const {
    if (derivOrder[0] == 1) {
        if (derivOrder[1] == 0)
            return 2.0*arguments[1];
        else if (derivOrder[1] == 1)
            return 2.0;
    }
    if (derivOrder[1] == 1 && derivOrder[0] == 0)
        return 2.0*arguments[0];
    return 0.0;
}
};
```

3 Appendix A

Lepton supports the following operators in expressions.

+	Add
-	Subtract
*	Multiply
/	Divide
^	Power

The following mathematical functions are built in. Others may be added using the CustomFunction class.

sqrt	Square root
exp	Exponential
log	Natural logarithm
sin	Sine (angle in radians)
cos	Cosine (angle in radians)
sec	Secant (angle in radians)
csc	Cosecant (angle in radians)
tan	Tangent (angle in radians)
cot	Cotangent (angle in radians)
asin	Inverse sine (in radians)
acos	Inverse cosine (in radians)
atan	Inverse tangent (in radians)
sinh	Hyperbolic sine
cosh	Hyperbolic cosine
tanh	Hyperbolic tangent
erf	Error function
erfc	Complementary error function
abs	Absolute value

min	Minimum of two values
max	Maximum of two values
delta	$\text{delta}(x) = 1$ if $x=0$, 0 otherwise
step	$\text{step}(x) = 0$ if $x<0$, 1 if $x\geq 0$

Numbers may be given in either decimal or exponential form. All of the following are valid numbers: 5, -3.1, 1e6, and 3.12e-2.

An expression may be followed by definitions for intermediate values that appear in the expression. A semicolon “;” is used as a delimiter between value definitions. For example, the expression

$$a^2 + a * b + b^2; \quad a = a1 + a2; \quad b = b1 + b2$$

is exactly equivalent to

$$(a1 + a2)^2 + (a1 + a2) * (b1 + b2) + (b1 + b2)^2$$

The definition of an intermediate value may itself involve other intermediate values. All uses of a value must appear *before* that value’s definition.
